Bypassing the cuffing effect in adult hypospadias surgery diversion

Hasan KOCOĞLU (*), Bilal Fırat ALP (**), Ercan MALKOÇ (***), Sami UGUZ (****)

SUMMARY
Urethral stents are frequently used for urinary diversion after hypospadias surgery. In this study, we aim to compare the results of no-balloon catheter (nelaton catheter) and modified foley catheter usage after TIPU operations in adults. The medical records of 53 adult patients who applied TIPU for subcoronal or midpenile hypospadias between November 2008 and September 2012 were evaluated retrospectively. Patients were evaluated in two groups based on the performed urinary diversion. Group 1 was composed of 29 patients to whom 16 F nelaton catheter was used for urinary diversion between November 2008-December 2010, whereas Group 2 consisted of 24 patients to whom 12 F foley catheter coated by 16 F nelaton catheter by half was used for urinary diversion between February 2011 – September 2012. There was no statistically significant difference between Group 1 and Group 2 in terms of age, the location of the mea, the number of secondary cases, the length of the neourethra, fistula and urethral stricture (p>0.05). Surgery success rate was 79.3% in Group 1 and 79.1% in Group 2 (p>0.05). At the 6th month follow-up, no statistically significant difference was found between two groups regarding fistula and urethral stricture. In terms of postoperative patient comfort, Group 2 were better than Group 1 (p<0.05).

Twelve F foley catheter, half of which is coated with 16 F nelaton catheter, could be used for diversion in TIPU operations in adult patients with distal and mid-shaft penile hypospadias to reduce postoperative patient discomfort.

Key words: Cuffing effect, Foley, Adult Hypospadias

Introduction
Hypospadias is believed to result from arrested penile development, leaving a proximal urethral meatus (1). The incidence of hypospadias is 1/300 in male children (2). But there is an increase of its incidence with considerable variation in different countries (3). Various surgical procedures have been described to correct this congenital condition. Since its introduction in 1994 by Snodgrass (4), the tubularized incised-plate urethroplasty (TIPU), a modification of the Thiersch-Duplay technique, has become a very popular repair for hypospadias; it is associated with very good functional and cosmetic results (5,6,7). Almost all the current published studies on TIPU encompassed pediatric series and are usually treated before school age in developed countries. However, in developing countries it is not uncommon for adults to present with hypospadias that has not been treated in childhood (7,8). Although the studies of stent-free repair using the TIPU presents excellent results (9-12), urethral stenting following hypospadias surgery offers some advantages: avoidance of obstruction secondary to postoperative edema; supporting repair and achieving urinary drainage; and prevention of leakage through suture lines with forceful urination (13).

Urethral stents are frequently used for urinary diversion after hypospadias surgery. The foley catheter is not generally preferred, for the formation of a ‘cuff’ on deflation of the balloon of all foley catheters that causes difficulty in removal (cuffing effect of balloon). Problems with catheter removal cause discomfort to the patient, with the risk of urethral trauma leading to stricture formation (14,15). In the literature, there is not comprehensive study on the usage of foley catheter for adult hypospadias surgery. We have recently been using the modified foley catheter that we designed in our patients.

In this study, we aim to compare the results of no-balloon catheter (nelaton catheter) and modified foley catheter usage after TIPU operations in adults.

Patients and methods
The medical records of 53 patients who applied TIPU for subcoronal or midpenile hypospadias between November 2008 and September 2012 were evaluated retrospectively. The patients who underwent hypospadias surgery more than twice, those who did not have a urethral plate of sufficient width; those with proximal hypospadias; those with chordees (except minimal chordees) and those who did not come to the follow-ups in the first six month were excluded from the study. Patients were evaluated in two groups based on the performed urinary diversion. Group 1 was composed of 29 patients to whom 16 F nelaton catheter was used for urinary
Preparation of the coated foley catheter: We vertically cut the nelaton piece that we obtained by dividing the 16 F nelaton catheter into two. Subsequently, we coated the half of the 12 F foley catheter with the 16 F nelaton piece (Figure 1). The half of one end of the new catheter we derived had a thickness of 12 F, while the half of the other end passing through the urethral scar line was 16 F thick. We determined that, at the end of one week after inflating the catheter balloon by 7-10 ml, the thickness of the balloon cuff was not more than 16 F (Figure 2).

The TIPU surgery was performed under spinal anesthesia as explained by Snodgrass. The penis was degloved. During degloving the penis, special care was taken to create good vascularized pedicle. After dividing the urethral plate in the midline, new urethra was formed with subepithelial transitive running suture technique, where 5/0 polyglactin suture was used. The length of the new urethra formed was noted for each patient. In the formation of the new urethra, nelaton or coated foley catheter, which would remain on the patient after the operation, was used. The patient was not catheterized again after the formation of the new urethra. In this way, we abstained from a trauma that might have developed on the suture line of the new urethra. The suture line of the new urethra was closed with good vascularized pedicle. Bleeding controls were held with 5/0 polygactin suture. Electrocauterisation never used for bleeding. In the patients that nelaton was used, catheter was fixed to the glans penis by gummy bandage (Coban). Urinary diversion was performed for 7 days for every patient. All patients were given oral antibiotics (second generation cephalosporin). In order to reduce the bladder contraction in those who had urine leakage at the edge of the catheter, 4 mg tolteradine was given until the termination of the diversion.

The patients were called for follow-up at the 1st, 3rd and 6th month of the first year. Patients who did not have any complication were called for follow up once a year after then. In the statistical evaluation held in the 6th month. When both fistula formation at the 8th day and scar line detachment were assessed, no statistically significant difference between Group 1 and Group 2 in respect to urethrocutaneous fistula existency and urethral stricture development. Statistical comparison of the success rates in Group 1 and Group 2 was evaluated by chi-square test. The p values < 0.05 were considered significant.

**Results**

There was 29 patients in Group 1 with a mean age 21.4 years. Urinary diversion was performed with nelaton catheter fixed to the glans penis. Twenty four of the cases were primary and 5 were secondary in this group. External urethral mea were located subcoronal in 22 patients and midpenil in 7.

The mean age of the 24 patients in Group 2 were 22.5 and urinary diversion was performed with coated foley catheter. The number of primary and secondary cases in this group was 20 and 4, respectively. External urethral mea were located subcoronal in 19 and midpenil in 5 patients. There was no statistically significant difference between Group 1 and Group 2 in terms of age, the location of the mea, the number of secondary cases, the length of the neourethra, fistula and urethral stricture (p>0.05) (Table 1).

could not be achieved in any of the patients given tolteradine. The reason for the partial response in Group 2 revealed partial response. Complete dryness was achieved in only 1 out of 2 patients in Group 1 and 1 out of 2 patients in Group 2. The reason for the partial response in Group 2 was due to the mobilization of a portion of the urethra and severe pain during morning erections. In order to reduce the aforementioned complaints, the bladder was emptied using a transurethral catheter or a portion of the catheter was hooked up while taking out or catheter was removed. In 2 patients, catheter was removed due to the mobilization of a portion of the catheter and severe pain during morning erections. To avoid the occurrence of urethral fistula and urethral stricture, the 5 ml balloon of the pediatric catheter is recommended to be inflated by 2 ml at maximum (27). Although the author suggests that the inflation of the balloon by 2 ml may prevent premature removal of the catheter, bladder leaks and the need for further special care to avoid inadvertent slippage are still encountered (12). These problems observed in pediatric patients were also seen in a high rate in our Group 1 patients. In adult patients, pain during morning erections was the main reason for the mobilization of a portion of the catheter and severe pain during morning erections.

Discussion

Hypospadias is a congenital anomaly in which urethral meatus opens proximal and ventral to the glans penis. More than 200 operations have been described for reducing the complication rate subsequent to the surgical procedure (16). The presence of chordae, quality of the urethral plate, experience of the surgeon, use of urinary diversion and dressing are very important for surgical success (13,17).

In order to overcome fistula and detachment of suture lines that urine might cause, urinary diversion is performed in hypospadias surgeries (18). Snodgrass had used intravesical stent for urinary diversion in TIPU operations (4). Recently, successful stent-free hypospadias surgery was reported in pediatric patients with distal and midpenile hypospadias (9-12).

According to the literature, there is no study on stent-free TIPU practice in adult patients with distal and midpenile hypospadias. In adult patients, mostly suprapubic or transurethral catheter is used for diversion. Nelon catheter is preferred as a transurethral catheter but foley catheter is used in selected patients. In adult patients, mobilization of a portion of the catheter or severe pain during morning erections are the main factors disturbing the patient comfort.

Snodgrass has recommended stent placement for about a week (4). In addition, it has been shown that urethral stent usage for more than 12-14 days in patients who underwent deep plate incision is not beneficial in the avoidance of complication development (28). Although there has been no data reported on the stent usage period for adult patients, general approach on the period for stent usage is 7-10 days.

In our series, the complication rates of urethral fistula and urethral stricture occurrence were similar to other studies (7,8, 19-21). Although urethral fistula and urethral stricture development rates seem to be lower in the group of patients that we used the coated foley catheter, no statistically significant difference was detected. Nonetheless, the patient comfort was statistically improved in Group 2.

There were several limitations in this study. As a retrospective study, the evidence was not as strong as that in a prospective randomized trial. However, we believe that the results of our study would give hints for future prospective studies.

Conclusion

Based on our preliminary experiences, we conclude that 12 F Foley catheter, half of which is coated with 16 F Nelaton catheter, could be used for diversion in TIPU operations.
adult patients with distal and mid-shaft penile hypospadias to reduce postoperative patient discomfort. Further randomized multicenter studies are required to verify our data.
